Supporting Information

ABSTRACT: Direct determination of mercury (Hg) speciation in sulfide-containing environments is confounded by low mercury concentrations and poor analytical sensitivity. Here we report the results of experiments designed to assess mercury speciation at environmentally relevant ratios of mercury to dissolved organic matter (DOM) (i.e., <4 nmol Hg (mg DOM)^{-1}) by combining solid phase extraction using C_{18} resin with extended X-ray absorption fine structure (EXAFS) spectroscopy. Aqueous Hg(II) and a DOM isolate were equilibrated in the presence and absence of 100 μM total sulfide. In the absence of sulfide, mercury adsorption to the resin increased as the Hg:DOM ratio decreased and as the strength of Hg-DOM binding increased. EXAFS analysis indicated that in the absence of sulfide, mercury bonds with an average of 2.4 ± 0.2 sulfur atoms with a bond length typical of mercury-organic thiol ligands (2.35 Å). In the presence of sulfide, mercury showed greater affinity for the C_{18} resin, and its chromatographic behavior was independent of Hg:DOM ratio. EXAFS analysis showed mercury—sulfur bonds with a longer interatomic distance (2.51—2.53 Å) similar to the mercury—sulfur bond distance in metacinnabar (2.53 Å) regardless of the Hg:DOM ratio. For all samples containing sulfide, the sulfur coordination number was below the ideal four-coordinate structure of metacinnabar. At a low Hg:DOM ratio where strong binding DOM sites may control mercury speciation (1.9 nmol mg^{-1}) mercury was coordinated by 2.3 ± 0.2 sulfur atoms, and the coordination number rose with increasing Hg:DOM ratio. The less-than-ideal coordination numbers indicate metacinnabar-like species on the nanometer scale, and the positive correlation between Hg:DOM ratio and sulfur coordination number suggests progressively increasing particle size or crystalline order with increasing abundance of mercury with respect to DOM. In DOM-containing sulfidic systems nanocolloidal metacinnabar-like species may form, and these species need to be considered when addressing mercury biogeochemistry.

INTRODUCTION

Predicting the fate and transport of soft, chalcophilic metals in the environment depends in part on metal speciation in the presence of sulfide and dissolved organic matter (DOM). The speciation of mercury (Hg) is of particular concern because of the potential formation of methylmercury (especially in sulfate-reducing systems) and bioaccumulation in aquatic food chains. Studies of other metals have identified nanocolloidal metal-sulfide minerals in sulfide-containing systems, including ZnS(s) in biofilms and at microbial interfaces, and CuS(s) in experimentally flooded wetlands and experimental systems containing DOM. Colloidal mercury-sulfide minerals, particularly metacinnabar (β-HgS(s)), the low-temperature polymorph of HgS(s), have been observed in experimental systems but not in natural sulfate-reducing environments with relatively low mercury concentrations and no point-source contamination.

Efforts to thermodynamically model the speciation of Hg(II) primarily focus on Hg-DOM complexes in the absence of sulfide and Hg-sulfide complexes in the absence of DOM. Provided the mercury concentration is sufficiently low, DOM exhibits a high affinity for Hg(II), dominating mercury speciation in typical oxic surface waters. The high strength of Hg-DOM interactions at low Hg:DOM ratios, coupled with directly observed mercury-soil organic matter binding sites, suggests DOM binding sites are thiol-like in nature, although the mercury coordination environment has never been directly observed in aquatic DOM as it has been in soil organic matter. Studies of mercury speciation with sulfide in the absence of DOM show rapid precipitation of metacinnabar and a number of dissolved mercury-sulfide complexes (e.g., HgHS_{2}^{2-}, Hg(HS)_{2}^{2-}, HgS_{2}^{2-}, HgS^{3-}), of which neutrally charged complexes have been hypothesized to be the most important for methylation.

Thermodynamic models that suggest mercury-sulfide complexes dominate mercury speciation at low mercury concentrations do not compare well with empirical observations of colloidal HgS(s) stabilized by DOM in experimental systems. In sulfide- and DOM-containing systems with a mercury concentration of 50 μM, metacinnabar particles were observed as particles or aggregates of less than 100 nm in diameter. At 50 nM Hg, the particles or aggregates, if present, were too small to remove via conventional centrifugation. Similar work using ultracentrifugation has demonstrated removal of mercury particles from solutions with concentrations as low as 1 nM Hg, although the removed mercury was only definitely characterized as metacinnabar-like at 10 μM Hg. The metacinnabar particles formed in the presence of DOM, sulfide, and relatively high concentrations of total mercury (i.e., >10 μM) become coated with DOM, which increases electrostatic repulsion and prevents aggregation and bulk precipitation of metacinnabar.

The direct observation of DOM-stabilized metacinnabar particles is limited to studies conducted at mercury concentrations far in excess of most natural systems, where only the weakest DOM binding sites are relevant for mercury speciation. Speciation calculations, however, suggest that DOM-stabilized HgS(s) may also be present at common environmental levels of mercury, DOM, and sulfide.

The goal of this study was to empirically determine mercury speciation in DOM-containing solutions with and without free aqueous sulfide at Hg:DOM ratios and total mercury concentrations that are lower than previously studied and span a range of Hg-DOM binding strengths. We adopted a solid phase extraction (SPE) method previously used to determine Hg-DOM binding constants to concentrate hydrophobic mercury species and applied this method over a wide range of Hg:DOM ratios. The speciation of mercury concentrated by SPE was subsequently examined with extended X-ray absorption fine structure (EXAFS) spectroscopy for samples of selected Hg:DOM ratios. The results presented in this paper provide direct insight into the nature of the Hg-DOM bond and on the role of DOM in mercury speciation in sulfidic environments.

## METHODS

### DOM Isolation

Whole water was collected from the F1 site (26°21′35.5″N, 80°22′14.4″W) in the Florida Everglades, filtered through a 0.3 μm glass fiber filter, acidified to pH 2 with HCl, and passed through a column of Amberlite XAD-8 resin according to the method of Aiken et al. The hydrophobic acid fraction (HPOA; comprised of humic and fulvic acids) was retained on the XAD-8 resin and eluted with 0.1 M NaOH. The eluate was hydrogen-saturated, desalted, freeze-dried, and stored for later use. This DOM isolate has been used in several studies of mercury-organic matter interactions. Information on the DOM source and characterization is available elsewhere.

### Experimental Solutions

Two identical sets of experimental solutions were prepared—a set for experiments only involving SPE and a set for SPE followed by EXAFS analysis of mercury on the resin. Experimental solutions for both sets were prepared in deionized water (±18.0 MΩ cm resistivity) and contained 0.01 M NaH2PO4, enough NaClO4 to bring the ionic strength to 0.1 M (as calculated by Visual MINTEQ) and an appropriate amount of 0.1 M NaOH to bring the pH to 6.5 ± 0.1. DOM stock solution was prepared daily, filtered (0.45 μm Supor membranes), and added to the experimental solutions to yield a DOM concentration of approximately 10 mg L⁻¹ for all SPE and most SPE-EXAFS experiments (measured range 8.6–11.3 mg DOM L⁻¹). Some of the SPE-EXAFS experiments were conducted at approximately 50 mg DOM L⁻¹. Appropriate volumes of Hg(II) stock solution (Hg(NO3)₂ in 10% HNO₃) were spiked into the experimental solutions to achieve mercury concentrations ranging from 0.35 nM to 1.4 μM. The range of mercury and DOM concentrations allowed some experiments to be conducted at a Hg:DOM ratio at or below 4 nmol Hg (mg DOM)⁻¹, the ratio at which all strong binding DOM sites become saturated and weak-binding sites begin to also bind mercury. Sulphide-containing solutions were prepared in an oxygen-free glovebox. Sodium sulfide (Na₂S·H₂O; washed before use) stock solution was prepared daily and added to experimental solutions to bring the total sulfide concentration to 100 μM. Solution bottles were wrapped with aluminum foil to prevent photoreactions and allowed to mix at room temperature on a shaker table rotating at 150 rpm. Solutions were equilibrated for 20–24 h, which has been shown elsewhere to give sufficient time for Hg-DOM equilibration and Hg-DOM-sulfide equilibration. Containers for solution/stock preparation and sampling were glass with Teflon-lined caps cleaned in a solution of 10% HNO₃ and 10% HCl (trace metal-grade) for at least 24 h and baked at 400 °C for 4 h.

### Solid Phase Extraction

The SPE portion of the experiments was carried out on glass columns (10 cm length, 0.9 cm diameter; Spectrum Chromatography) packed with 0.500 g of C₁₅₈ resin (Supelclean ENV-18, Spectraorp). The column fittings and lines were Teflon, except for the pump tubing, which was polyvinylchloride. Resin-free columns and tubing were cleaned with a mixture of 10% HNO₃ and 10% HCl and rinsed repeatedly with deionized water. Clean resin was prepared in the column by suspending resin in methanol and rinsing (20 min per rinse at 4 mL min⁻¹) with deionized water followed by 5 mM HCl, repeating once, and concluding with deionized water. The loss of mercury to a resin-free column (<5%) and contamination from a resin-filled column (<0.03 mM) were sufficiently small to be ignored in the subsequent SPE experiments, but there was some DOC contamination from resin-filled columns (<5 mg C L⁻¹; presumably methanol).

Cleaned and resin-filled columns were loaded with approximately 1 L of experimental solution for SPE experiments and 2 L of solution for SPE-EXAFS experiments. Experimental solutions were pumped through the cleaned resin-filled columns at a flow rate of 4.0 ± 0.2 mL min⁻¹. After expunging the first 2 mL of solution out of each column, the remaining loaded volume was collected as effluent fractions for chemical analyses. Resin was harvested from the column following solution loading and was stored under an oxygen-free atmosphere for sulfide-containing experiments until EXAFS analysis. Mercury recovery from the SPE experiments, including mercury in effluent fractions and mercury adsorbed to the resin, was greater than 90% of the total mercury loaded. Error in the SPE of mercury was related to errors in mercury measurements (described in next section) and depended on the amount of mercury passing through the resin. At high retentions (>90%) the error was less than 1% retained mercury, and at lower retentions (~60%) the error was approximately 4% retained mercury.

### Sample Analysis

Dissolved organic carbon (DOC) concentrations were determined using a total organic carbon analyzer (OI Analytical Model 700). DOM concentrations were calculated based on DOC measurements and the carbon content of
the Everglades F1 HPoA isolate (52.2% C by mass). Measurements of ultraviolet and visible light absorbance at wavelengths ranging from 254 to 412 nm were made using a UV–visible spectrophotometer (Agilent model 8453) with a 1 or 5 cm path length quartz cuvette.

Total aqueous mercury concentrations in initial and effluent samples from the SPE were determined by cold vapor atomic fluorescence spectroscopy using a Millennium Merlin mercury analyzer according to EPA Method 245.7. Analytical mercury stocks were prepared from National Institute of Standards and Technology (NIST) standard reference material 3133. Mercury standards and most samples were oxidized with 1% (v/v) KBr/KBrO₃ solution. High DOM and sulfide-containing samples were oxidized with 2% (v/v) KBr/KBrO₃ solution to ensure sufficient residual oxidant to preserve mercury after oxidation of organic matter and sulfide species. Acceptable recovery of standards was 80–120% with less than 20% relative difference in duplicate measurements. Typical recovery was 90–110% with less than 10% relative difference. The detection limit for any given run was always below 0.013 nM Hg based on three standard deviations of seven replicates of a sample with a concentration one-half of the lowest standard.

Solid phase mercury concentrations on the harvested chromatography resin were measured on a DMA-80 direct mercury analyzer (Milestone Inc.) by thermal decomposition of the sample, catalytic conversion to elemental mercury, amalgamation, and atomic absorption. Calibration was done with a series of standard reference materials obtained from NIST and Environment Canada. Acceptable recovery of the reference materials was 80–120%.

Extended X-ray Absorption Fine Structure Spectroscopy. Resin samples were prepared for EXAFS by loading 2 L of the experimental solutions outlined in SI Table 1 onto C₁₈ resin. Two liters of solution were necessary to maximize the amount of mercury loaded onto the resin due to the relatively high concentration threshold (approximately 40 ppb Hg) needed to collect viable EXAFS spectra. The top third of the resin in the column was removed from the column and used for EXAFS analysis because solid phase mercury analysis indicated it was more concentrated than the resin in the bottom two-thirds of the column.

EXAFS data were collected on wiggler beamline 11–2 at the Stanford Synchrotron Radiation Lightsource using a Si(220) monochromator crystal in the φ = 90° crystal orientation. Mercury L₃-edge EXAFS spectra were collected using an aluminum coldfinger liquid nitrogen cryostat (77 K) to minimize thermal vibration and improve the quality of the spectra from low mercury concentration samples. The resin samples were loaded into aluminum holders in an oxygen-free environment, enclosed in Kapton tape, and quickly transferred to the liquid nitrogen cryostat to minimize exposure to oxygen. Spectra were collected on a 32-element high-throughput germanium detector in fluorescence-yield mode. Gallium filters were used to minimize interference from inelastic scattering. HgCl₂ was used as an internal standard for energy calibration of each spectrum collected.

Multiple scans (13–22) were collected for each sample, energy-corrected using the calibration standard, deadtime-corrected for potential loss of signal due to finite photon detection times, and averaged together. After background subtraction, the data were converted to k-space with a k²-weighting and Fourier-transformed. The EXAFS spectra were fit over a k-range of 2.0–9.5 Å⁻¹ using phase and amplitude functions from model single-shell scattering paths generated in SIXPack using Feff6. Hg—C, Hg—O, and Hg—S models (the only realistic first shell interactions in Hg-DOM-sulfide systems) were created and constrained based on the results of the first shell fitting of the resin samples. Mixed interactions were attempted (i.e., Hg—O and Hg—S), but single atom interactions consistently proved to be better fits. Given the limited energy range over which spectra were resolvable, only first shell fitting was successfully completed for each resin sample. The scale factor (S₀) was fixed at 0.9 for all samples, and the Debye—Waller factor (σ²), which serves as a measure of thermal vibration and static disorder around mercury in the sample, was first allowed to float for all fits; the average Debye—Waller factor for all samples (0.007 Å²) was selected and final fits fixed at this value in order to directly compare fitting results between samples.

### RESULTS

**DOM Solid Phase Extraction.** The absorption of ultraviolet and visible (UV–vis) light was used to track DOM adsorption to the C₁₈ resin because small amounts of methanol contamination in effluent fractions led to erratic DOC measurements. DOM retention by the resin was consistent regardless of mercury concentration (0.35 nM–1.4 μM) or the presence or absence of sulfide (Figure 1a). DOM retention decreased as the volume of loaded solution increased (SI Figure 1). The fraction of UV–vis-absorbing components retained by the resin increased with increasing wavelength but was generally low — less than 35%. The UV–vis absorbance of DOM at 254 nm correlates well with the aromaticity of the organic matter, although more conjugated molecules are expected to absorb at 412 nm. These data indicate that the more conjugated organic molecules are also somewhat more hydrophobic and preferentially adsorb to the resin.

**Mercury Solid Phase Extraction.** Retention of mercury by C₁₈ resin was a function of mercury concentration and the presence or absence of sulfide (Figure 1b), unlike the retention of DOM. Mercury adsorption to the column did not change substantially through the course of loading up to 1 L of sulfide-free solution (SI Figure 2). The overall efficiency of mercury adsorption from sulfide-free solutions was dependent on the mercury concentration in the loading solution (Figure 1b). At 5.6 nM Hg and below, the retention of mercury was 85–91%. At 39 nM Hg and above, retention dropped to 48–61%.

Retention curves for mercury in systems containing 100 μM total sulfide were distinctly different from those without sulfide (SI Figure 2). The retention of mercury from a sulfide-containing solution with 0.45 nM Hg increased as the total volume loaded increased. In contrast, at mercury concentrations from 1.5 to 490 nM, the mercury adsorption was consistently high (Figure 1b, SI Figure 2). Based on these chromatography results, the mercury species formed in the presence of sulfide at higher mercury concentrations are slightly more hydrophobic (>99% retention at 490 nM) than those formed at lower mercury concentrations (95% retention at 1.5 nM) and substantially more hydrophobic than those formed in the absence of sulfide. For all cases, greater than 60% of the mercury retained by the resin was present in the top one-third of the column based on solid phase analysis.

The 0.45 nM Hg and sulfide solution resulted in uncommon chromatographic behavior — the retention of mercury increased as the volume of solution loaded onto the resin increased. Such behavior indicates that the sorbent phase becomes more favorable for the sorption of the compound in solution as the amount...
of the sorbed compound increases. In the mercury-DOM-sulfide systems in this study, two components are accumulating on the resin—mercury and DOM—and either could be responsible for the increased retention of mercury with loaded volume. Either the adsorption of mercury from solution could promote the sorption of more mercury, which could potentially lead to the formation of mercury species on the resin which are not present in solution, or the adsorption of DOM from solution could promote the adsorption of more DOM along with the bound mercury species.

To determine which mechanism was responsible for the increasing mercury retention with increased loading, we compared the retention of mercury from the 0.45 nM Hg, 100 μM sulfide, 10.6 mg DOM L$^{-1}$ solution with the retention of mercury after the resin was preloaded with DOM (Figure 2). A mercury-free preloading solution (9.8 mg DOM L$^{-1}$, 100 μM sulfide, 428 mL) was loaded onto C$_{18}$ resin and followed with an identical solution that also contained 0.40 nM Hg. The DOM retention was identical in both systems as indicated by the retention of UV$_{254}$ absorbing components (Figure 2). After preloading the resin with DOM, mercury retention was initially very high (>97%), and the retention did not increase with increased loading volume as observed in the system without preloading. We interpret the difference in mercury retention to mean that mercury—mercury interactions were not driving mercury retention because the DOM-preloaded system showed high mercury retention at the beginning of mercury loading. Had mercury retention increased with volume after DOM preloading, there would have been evidence for mercury—mercury interactions, which would have brought into question whether the mercury species on the resin are present in solution. Instead, we surmise that DOM served as a bridge between the mercury species in solution and the resin, and an abundance of DOM on the resin increased mercury affinity for the sorbent phase.

**Extended X-ray Absorption Fine Structure Spectroscopy.**

Experimental and fitted mercury L$_{III}$-edge EXAFS spectra and the Fourier transforms corresponding to the conditions outlined in SI Table 1 are shown in Figure 3. The EXAFS spectra of the three sulfide-containing systems (Figure 3b, 3c, and 3d) are in phase with one another and out of phase with the sulfide-free sample (Figure 3a). This corresponds with the alignment of the primary Fourier transform features of the sulfide-containing samples (indicated in Figure 3 by a vertical line) and the misalignment of the sulfide-containing samples with the sulfide-free sample. The spectra for samples with added sulfide (3b, 3c, and 3d) were best modeled by a mercury—sulfur bond in the first shell with a Hg—S interatomic distance of 2.51—2.53 Å (±0.01—0.02 Å, depending on the sample; Figure 3). The mean sulfur coordination number for the sulfide-containing samples increased with increasing Hg:DOM ratio from 2.3 ± 0.2 sulfur atoms at 1.6 nmol Hg (mg DOM)$^{-1}$ to 3.3 ± 0.2 sulfur atoms at 34 nmol Hg (mg DOM)$^{-1}$. The spectra for the sample without added sulfide (3a) was also best modeled by mercury—sulfur bonds in the first shell, despite the absence of added sulfide in the sulfide-free system. The Hg-DOM interaction was fit with a significantly shorter Hg—S distance of 2.35 ± 0.01 Å and a coordination number of 2.4 ± 0.2 sulfur atoms.
Figure 3. $k^2$-weighted mercury L_{III}-edge EXAFS, Fourier transforms, and fitting results for collected spectra (solid) and fits (dashed) for the four SPE-EXAFS samples: (a) sulfide-free at a Hg:DOM ratio of 4.0 nmol Hg (mg DOM)$^{-1}$; (b, c, and d) 100 μM total sulfide and Hg:DOM ratios of 1.9, 4.9, and 34 nmol Hg (mg DOM)$^{-1}$, respectively. Solution chemistries are summarized in SI Table 1. All spectra are best fit by a Hg–S interaction. The sulfur coordination number (CN) and average bond distance (R) are noted for each sample with the 95% confidence interval (±2σ). The Debye–Waller factor ($σ^2$) was fixed at 0.007 Å$^2$ for all four fits.

■ DISCUSSION

Mercury-Dissolved Organic Matter Interactions. In the absence of sulfide and at sufficiently low Hg:DOM ratios, we hypothesized that Hg-DOM binding would be dominated by mercury–sulfur interactions because (1) Hg-DOM binding studies have measured large stability constants consistent with thiol-like sites$^{13,15}$ and (2) Hg-soil organic matter (SOM) studies using EXAFS spectroscopy have detected Hg–S bonds at low Hg:SOM ratios.$^{20,40}$ We observed 2.4 coordinating sulfur atoms at 2.35 Å, which is consistent with observations of a 2–3 sulfur coordination environment in soil organic matter and soil humic acid as detected by X-ray spectroscopy$^{21,40}$ and pH titrations.$^{19}$ The Hg–S interatomic distance is in good agreement with two-coordinate mercury binding environments observed for model thiols$^{41}$ and represents the first known direct observation of mercury binding environments in aquatic DOM. Sulfur is a relatively minor element in DOM (1.7 wt% in the isolate used in this study), and the proportion of sulfur that is actually involved in metal binding is low (<2% of the total sulfur in this isolate based on 2.4 atoms/site and a binding capacity of 4 nmol (mg DOM)$^{-1}$. Multiple sulfur atoms per site suggests the possibility that these sites may be (1) of biological origin (e.g., thiols in protein residues), (2) the result of abiotic sulfur incorporation into DOM, or (3) the result of multiple DOM molecules coordinating a mercury atom.

The concentration requirement, or detection limit, of EXAFS restricted identification of the Hg-DOM binding environment to a Hg:DOM ratio of 4.0 nmol Hg (mg DOM)$^{-1}$, which is the strong binding capacity of the DOM isolate.$^{13}$ Hg:DOM ratios in most environmental settings are typically a few orders of magnitude lower than this strong binding capacity. The chromatographic data suggest we can extrapolate information gained at the Hg:DOM ratio of 4.0 nmol Hg (mg DOM)$^{-1}$ to lower and more environmentally relevant Hg:DOM ratios. The sulfide-free data in Figure 1b show high retention of mercury (>85%) at mercury concentrations below 5.6 nM Hg and lower retention of mercury (<62%) at mercury concentrations above 39 nM Hg. When normalized to the DOM content of each system (all had approximately 10 mg DOM L$^{-1}$), the transition observed between 5.6 and 39 nM Hg corresponds to a transition between 0.67 and 4.6 nmol Hg (mg DOM)$^{-1}$.

Below the 4 nmol Hg (mg DOM)$^{-1}$ strong binding capacity of the DOM, the Hg-DOM complexes are significantly more hydrophobic with respect to the C$_{18}$ resin than they are above the strong binding capacity. The transition from more to less hydrophobic complexes as the Hg:DOM ratio increases past 4 nmol Hg (mg DOM)$^{-1}$ corresponds to the transition from thiol-like Hg-DOM binding strengths to carboxyl-like Hg-DOM binding strengths.$^{19}$ Both types of complexes are significantly more hydrophobic than the mercury-free DOM, which is only retained at about 20% as measured by the retention of UV$_{254}$ absorbing components (Figure 1a). The sulfur dominated binding environment observed with EXAFS at 4 nmol Hg (mg DOM)$^{-1}$ is likely only present in a small subset of DOM molecules and that subset is more hydrophobic than other portions of the DOM pool. The chromatography data shown in Figure 1b, coupled with our understanding of DOM binding strengths, suggests that the small number of DOM molecules involved in the directly observed sulfur dominated mercury binding at 4 nmol (mg DOM)$^{-1}$ persist at lower, more environmentally significant Hg:DOM ratios where EXAFS was not possible.

Mercury-Dissolved Organic Matter-Sulfide Interactions. The EXAFS spectra from all three sulfide-containing samples were best fit with a Hg–S scattering interaction at an interatomic distance of 2.51–2.53 Å (Figure 3). The Hg–S interatomic distance from all three samples agrees, within uncertainty, with the 2.53 Å Hg–S distance in crystalline metacinnabar.$^{22}$ The observed EXAFS spectra are not consistent with cinnabar (which has six coordinating sulfur atoms at three distinct distances$^{22}$), polymeric HgS species that exhibit two sulfur atoms at a shorter distance of 2.30 Å,$^{26}$ neutrally charged complexes (i.e., HgS(aq) and HgHSO$_3$(aq)) with a single Hg–S interaction at less than 2.40 Å,$^{22}$ nor the Hg-DOM interaction described previously. In addition, simultaneous fits of a Hg–S scattering path at 2.53 Å indicative of metacinnabar and a Hg–S scattering path at 2.35 Å
indicative of Hg-DOM complexes showed no significant DOM binding in systems that contained sulfide.

The Hg–S bond distance is independent of Hg:DOM ratio for the three sulfide-containing samples and matches well with metacinnabar, but the sulfur coordination numbers are all lower than the four-coordinate structure of crystalline metacinnabar. The modeled coordination numbers may be explained by imperfectly ordered crystal structures or nanosized HgS(s) particles where under-coordinated mercury atoms on the particle surface comprise a large percentage of all mercury atoms in the phase. The disorder in the particles may even be greater than the coordination number implies because the Debye–Waller factor was fixed in the EXAFS modeling, which implicitly assumes that changes in the spectra were related to changes in coordination number and not the degree of disorder. The modeled coordination number increases with increasing Hg:DOM ratio (Figure 3, samples b, c, and d), which suggests that the Hg:DOM ratio is an important factor in dictating the size or crystalline order of the metacinnabar-like species. Metacinnabar-like species formed at the lowest Hg:DOM ratio resemble the initial phases of metacinnabar crystallization characterized by under-coordinated mercury atoms, whereas the metacinnabar-like species formed at the highest Hg:DOM ratio resembles a structure approaching that of bulk crystalline metacinnabar.22 The interaction of DOM with particle surfaces and subsequent control of particle aggregation has been documented for HgS(s)7–9 and other metal sulfides and metal oxides (e.g., refs 6 and 42), although the formation of HgS(s) has never been directly observed at the mercury concentrations and Hg:DOM ratios at which mercury is interacting with the strongest DOM binding sites. The strong DOM binding sites are not strong enough to prevent the formation of metacinnabar, but the metacinnabar that forms when mercury speciation is dominated by thiol sites is smaller or less ordered than metacinnabar formed at higher Hg:DOM ratios.

Our results show that the portion of DOM interacting with the surface of HgS(s) and preventing growth is more hydrophobic with respect to fractionation on C18 resin than the DOM that remains in solution. The majority of the DOM in our SPE experiments passed through the column, although the portions of the DOM that absorb light at higher wavelengths, which presumably represents greater conjugation, are retained on the resin. The minimum Hg:DOM ratio for metacinnabar formed at higher mercury concentrations.9 The results presented here contrast with the conclusions of octanol–water partitioning studies which suggest neutrally charged species (e.g., HgS0 and Hg(SH)2) dominate mercury speciation in the presence of sulfide in natural environments.24 DOM significantly alters the octanol partitioning of Hg–S species when mercury concentrations are as low as 0.1 nM.36 and the partitioning of amorphous metacinnabar-like nanoparticles to octanol has been demonstrated at a mercury concentration of 3 μM.9 Our study bridges the concentration divide by empirically observing a metacinnabar-like species at an intermediate mercury concentration, which chromatography suggests is present at even lower mercury concentrations than could be directly observed with EXAFS. Mercury-sulfide speciation modeling predicts metacinnabar will form at the intermediate and high mercury concentrations used in this study. However, the speciation modeling is ambiguous at the low concentrations in this study below about 4 nM Hg because of the uncertainty in thermodynamic constants (constants for the modeling reproduced in SI Table 2). If metacinnabar is not formed below 4 nM, then speciation modeling predicts hydrophilic complexes (primarily HgHS2−) will dominate in these systems (quantitative speciation presented in SI Figure 3). Hydrophilic complexes will not be retained by the C18 resin. Our data show the mercury species in sulfide systems are consistently retained at high levels by the resin, which indicates that the HgS(s) observed at higher mercury concentrations also dominates at lower, more environmentally relevant concentrations. Modeling efforts elsewhere have shown that uncertainty in thermodynamic constants, particularly the metacinnabar solubility product, makes mercury speciation difficult to predict at environmentally relevant concentrations.9 Our results provide empirical evidence that a discrete inorganic metacinnabar-like phase is stabilized by dissolved organic matter at mercury concentrations and Hg:DOM ratios that are more representative of natural systems.

Environmental Implications. Conventional filtration methods are insufficient to diagnose the presence or absence of nanosized particles in the environment; however, the potential exists to use a chromatographic approach to detect the presence of mercury-containing nanoparticles. Hsu-Kim and Sedlak25 noted the adsorption of mercury species to C18 resin when a wastewater effluent sample was exposed to sulfide. As that study and another9 have noted, some of those mercury species are not labile to a strong competing ligand, such as glutathione, whereas dissolved complexes with organic matter are labile. Now that direct observation of mercury speciation has identified metacinnabar (or at least, a metacinnabar-like phase) as a potential source of that nonlabile portion at lower mercury concentrations approaching environmentally relevant concentrations, the potential exists to identify similar species in natural anoxic waters with a chromatographic approach.

Knowledge of the speciation of mercury is paramount in assessing the extent and kinetics of the biologically driven conversion of
mercury into methylmercury. While this study does not attempt to determine the role of speciation in methylation, it provides evidence that sulfate-reducing microbes, which typically reside in sulfide- and organic matter-rich environments, are likely to be exposed to disordered, nanoparticulate metacinnabar stabilized by dissolved organic matter. Our results are consistent with the observation of poorly crystalline, nanometer-scale HgS(s) particles in a mercury contaminated site and illuminate the role of DOM in HgS(s) formation and stabilization. The mechanism of that stabilization, the rate of nanoparticle growth and aggregation, and the role DOM-coated nanoparticulate metacinnabar plays in methylation are critical areas for further research. In addition, the thermodynamics of a nanoparticulate phase are not necessarily well represented by thermodynamic constants of the bulk phase, and thus mercury speciation models may need to account for disordered nanoparticulate HgS(s).
